Summary

Inelastic neutron scattering (INS) is a spectroscopic technique used to measure the magnetic excitations in materials with interacting electron spins. The task of fitting the data gained from INS experiments can be formulated as an inverse eigenvalue problem (IEP), where the matrix formed represents the spin Hamiltonian of the sample molecule. INS_IEP is a MATLAB package that uses deflated numerical optimisation techniques to systematically find multiple solutions to this IEP. The package requires and is fully compatible with easyspin (Stoll & Schweiger, 2006), a package for solving similar problems in electron paramagnetic resonance.

Statement of need

Neutrons are an excellent bulk probe of material properties since they carry no charge and therefore penetrate deeply into matter. Neutrons also carry a quantum spin of a half, making them a sensitive probe of magnetism (Squires, 2012). Reactors and spallation sources with dedicated high-flux neutron sources serve the international research community with neutron scattering experiment capabilities for material research. Inelastic neutron scattering (INS) is one such experimental technique that can be used to study magnetism. In an INS experiment, a sample under investigation is irradiated with a beam of neutrons and the scattered neutron energy and momentum transfer are detected. For samples composed of finite-size clusters of magnetic moment-carrying atoms, such as single ions or molecular-based magnets, the detected neutron energy transfer gives direct access to the quantum spin excitations (M. Baker & Mutka, 2012; Furrer & Waldmann, 2013; "Spectroscopy Methods for Molecular Nanomagnets," 2014).

The energy of such excitations relates to the energy difference between eigenvalues of the Hamiltonian matrix that describes the quantum spin dynamics of the compound in question. Single-ion and molecular-based magnets are studied as prototype components (quantum bits, sensors) for quantum technologies. INS can therefore provide crucial information concerning the precise quantum properties of such systems. However, to relate the INS experimental results to the Hamiltonian that describes quantum spin dynamics requires parameterisation of matrix elements such that a set of eigenvalues and eigenstates matching the experiment are determined. This situation is known as the inverse eigenvalue problem.

To date, this problem is addressed in an iterative process where parameters of the Hamiltonian are varied manually, often one at a time, and the resultant eigenvalues compared to the experimental values - each such iteration requires an eigendecomposition of the Hamiltonian matrix. INS_IEP presents an elegant solution to solving this problem, using algorithms to calculate multiple parameter sets that minimise the difference in eigenvalues, reducing the number of Hamiltonian matrix diagonalisations, and providing a more robust method to reliably extract an accurate spin Hamiltonian model from INS experimental data.

41 Key Concepts

42 The Spin Hamiltonian

43 The Spin Hamiltonian, H , is an approximation of the Hamiltonian that uses spin coordinates
44 instead of orbital coordinates, and is widely used to model data arising from many spectroscopy
45 techniques (Launay & Verdaguer, 2014). It can be modeled as a linear combination of
46 interaction terms; in this package we will use the zero field interaction, H_{ZFI} , and the
47 electron-electron interaction, H_{EEI} :

$$H = H_{ZFI} + H_{EEI}.$$

48 Both of these terms can themselves be modelled as the linear sum of other basis matrices.
49 The zero field interaction can be written as:

$$H_{ZFI} = \sum_{-k \leq q \leq k} B_k^q O_k^q$$

50 where the O_k^q are Stevens Operators (Rudowicz & Chung, 2004), and B_k^q the associated
51 parameter. When there are multiple spin centres it is necessary to take Kronecker products of
52 the operator with identity matrices of the appropriate for each other spin centre.

53 When there are multiple spin centres it is also necessary to include an electron-electron
54 interaction term, H_{EEI} . This term will be the sum of interaction terms between each pair of
55 spin centres:

$$H_{EEI} = - \sum_{i \neq j} J_{ij} S_i \cdot S_j$$

56 where S_i is the vector of spin operators $S_i = [S_x, S_y, S_z]$ for the i -th spin centre, and J_{ij} is
57 the parameter to be found that represents the strength of interaction between the two spin
58 centres. Note that in the isotropic case J can be thought of as a scalar value, but in the
59 anisotropic case will be a matrix where the off diagonals are skew symmetric (often the off
60 diagonals are assumed to be zero). While the summation is in theory over all spin centre
61 combinations, in practice many of these contributions will be negligible - often only the nearest
62 neighbour interactions are modeled.

63 It is important to mention that these matrix operators can be very large. The size is defined
64 by the number of spin centres (n) and the spin (S_i) of each on, where the dimension is given
65 by:

$$\prod_i^n (2S_i + 1).$$

66 The operators are however highly sparse, this means that it is possible to use eigensolvers that
67 can take advantage of this sparsity.

68 Inverse Eigenvalue Problem

69 The INS experiments provide eigenvalues of the Spin Hamiltonian matrix of the sample, the
70 task of calculating the matrix from the eigenvalues is an inverse eigenvalue problem:

71 Let $A(x)$ be the affine family of matrices,

$$A(x) = A_0 + \sum_{i=1}^{\ell} x_i A_i,$$

where $x \in \mathbb{C}^\ell$ and $A_0, \dots, A_\ell \in \mathbb{R}^{n \times n}$ are linearly independent Hermitian matrices, and denote the ordered eigenvalues of $A(x)$ as $\lambda_1(x) \leq \dots \leq \lambda_n(x)$. Then the least squares inverse eigenvalue problem is to find the parameters $x \in \mathbb{R}^\ell$ that minimises

$$F(x) = \frac{1}{2} \|r(x)\|_2^2 = \frac{1}{2} \sum_{i=1}^m (\lambda_i(x) - \lambda_i^*)^2$$

where $\lambda_1^* \leq \dots \leq \lambda_m^*$ are the experimental eigenvalues (Chen & Chu, 1996). In the case of INS fitting the A_i basis matrices will be a combination of Stevens operators and electron-electron exchange terms. The IEP described above is formulated as an least squares problem because the number of eigenvalues that can be probed by INS experiments is often a small subset of the full spectrum. Due to the low temperatures that these experiments are performed at (can be as low as 1K) it is always the smallest eigenvalues that are involved. Note also that since it is the energy difference between the eigenvalues that is probed we actually have to modify the IEP - either by adding an additional parameter (an identity matrix) that shifts the values of the eigenvalues, or by changing the above formula for F to directly sum the difference in eigenvalues thereby reducing the number of residual equations in $r(x)$ by one.

As far as we are aware this is the first time that the fitting of INS data has been explicitly formulated as an IEP. An advantage of this formulation is that there are explicit formulas for the derivatives of $r(x)$. The first derivative (Jacobian) is:

$$J_r(x) = \begin{pmatrix} q_1(x)^T A_1 q_1(x) & \dots & q_1(x)^T A_\ell q_1(x) \\ \vdots & \ddots & \vdots \\ q_m(x)^T A_1 q_m(x) & \dots & q_m(x)^T A_\ell q_m(x) \end{pmatrix},$$

88 and the second derivative (Hessian) is:

$$(H_r)_{ij} = 2 \sum_{k=1}^m (\lambda_k - \lambda_k^*) \sum_{\substack{t=1 \\ \lambda_t \neq \lambda_k}}^m \frac{(q_t^T A_i q_k)(q_t^T A_j q_k)}{\lambda_k - \lambda_t}.$$

Another advantage is the number of constraints to fit is much smaller than fitting the spectrum itself, as it correspond to fitting only the locations of the peaks of the spectrum.

91 **Methods**

92 All of the methods used are iterative schemes of the form $x^{k+1} = x^k + p^k$ where the step p^k
93 uniquely defines each algorithm:

- Newton's method: $p^k = (J_r^T J_r + H_r r) - 1 J_r^T r$ (Nocedal & Wright, 2006)
- Gauss-Newton method: $p^k = (J_r^T J_r)^{-1} J_r^T r$ (Nocedal & Wright, 2006)
- Lift and Projection Method: $p^k = B^{-1} J_r^T r$ (Bloor Riley et al., 2025a)

Where the matrix B is the Gram matrix formed from the frobenius inner products of the basis matrices: $B_{ij} = \langle A_i, A_j \rangle_F$. The Lift and Projection method is a Riemannian Gradient descent method (Bloor Riley et al., 2025a), specifically designed for solving IEPs. In (Bloor Riley et al., 2025a) it is proven that the method is a strictly descending algorithm, that is it reduces the value of the objective function every step. Both the deflated Gauss-Newton method and the Riemannian Gradient descent Lift and Projection method are new methods designed for this package (Bloor Riley et al., 2025a, 2025b).

104 **Deflation**

The number of eigenvalues that can be probed via INS experiments varies depending on the equipment and sample in question, meaning that the fitting problem is often under or even

over determined. The IEP is also highly nonlinear and due to the experimental nature of the data may be ill-posed. One consequence of this is that the solution space may be very 'bumpy', that is there may exist many local minimisers to the problem. For example in Figure 1, there are clearly 4 distinct solutions (for more details see Example 1 and the file Example1_Mn12.m in the examples folder). We seek to solve the problem of multiple local minima by the use of Deflation, a numerical technique used to find multiple solutions to systems of equations (Farrell et al., 2015). Fortunately it is cheap to apply deflation for the above methods, it is simply a change to the length of the step - notably this means that the direction of each step does not change. It is proven in (Bloor Riley et al., 2025b) that the deflated methods will not converge to deflated points. The usual requirements still apply to the convergence of the new methods - that the initial guess is close enough to the new minimum, and that the Jacobian is full rank in a neighbourhood around that minimum. The rate of convergence of the deflated methods is also more complicated, although the number of iterations required to converge can go up with the number of deflations this is not a strict correlation, as can be seen in Figure 2.

Figure 1: Contour plot of how F varies with the two parameters B_2^2 and B_4^4 for the molecule Mn_12 as described in Example 1. There are four locally minimising parameter pairs corresponding to the four blue regions

Figure 2: Comparison of the convergence behaviour for computing each solution in Example 1. The gradient of the lines as the method approaches the solution shows how the methods are quadratically convergent local to a minimum.

Examples

Example 1 - Mn12

The first example we will look at is Manganese-12-acetate. This is a well known example in the INS and magnetism community, as one of the first molecules that behaves like a nano-sized magnet with a molecular magnetic coercivity as well as its role in the research of quantum tunnelling of magnetisation (Friedman et al., 1996; Sessoli et al., 1993).

The Spin Hamiltonian of this system, using the giant spin approximation, can be represented as a 21×21 matrix modelled using 4 Stevens operators (Bircher et al., 2004):

$$H = B_2^0 O_2^0 + B_4^0 O_4^0 + B_2^2 O_2^2 + B_4^4 O_4^4 \in \mathbb{R}^{21 \times 21}$$

We utilise the same spin system syntax as easyspin, so to set up the problem we first set up the model, along with initial guesses for the parameters:

```
%One spin centre (because giant spin approximation)
Sys0.S=10;
%Four Stevens operators
Sys0.B2 = [-100,0,-1000,0,0];
Sys0.B4 = [-1,0,0,0,-1,0,0,0,0];
```

Then we input the experimental eigenvalues - these are typically shifted such that the smallest eigenvalue is zero - and define which parameters to fit. Note that all values given must be in Hertz, so it may be useful to use conversions.

```
rcm = 29979.2458; meV = rcm*8.065; %Conversions values
%Input calculated eigenvalues:
Exp.ev = [0,0,1.24,1.24,2.3,2.3,3.18,3.18,3.91,3.91,4.5,4.5,4.97,4.97,5.32,5.32,5.54,5.54,5.54,5.54,5.54];
```

```
%Vary all non zero parameters (no Fixed parameters):
Vary = Sys0;
```

134 Then all that is required is to call INS_IEP with these three inputs:

```
SysOut = INS_IEP(Sys0,Vary,Exp);
```

135 If we wish to find all four solutions as shown in Figure 1 then we use the additional option:

```
Opt.NDeflations = 4;
SysOut = INS_IEP(Sys0,Vary,Exp,Opt);
```

136 In this case SysOut will be an array of four spin structures each containing a distinct locally optimal solution. It is possible to access information about the convergence of each deflation by using SysOut.Output. For example by utilising the iterates recorded, stored in SysOut.Output.Iterates it is possible to plot a graph of convergence, as can be seen in Figure 2. The Output structure also contains the value of F at the final point, as well as the number of iterations it took to get there.

142 Example 2 - Chromium(iii) Horseshoes

143 The second example concerns antiferro-magnetically coupled chromium(III) chains six atoms long (M. L. Baker et al., 2011), although different length chains are of interest and can also be modelled. Because there are multiple spin centres an electron-electron interaction term is required. The spin hamiltonian is a 4096×4096 matrix composed of two Stevens operators and one interaction term, since it is known a priori that each spin centre will have the same value parameters we will pin the parameters here, by setting the initial guess as the same value:

```
Sys0.S = [1.5 1.5 1.5 1.5 1.5 1.5];
Sys0.B2 = [1 0 -1 0 0;
           1 0 -1 0 0;
           1 0 -1 0 0;
           1 0 -1 0 0;
           1 0 -1 0 0;
           1 0 -1 0 0];
Sys0.J = [100,0,0,0,0,100,0,0,0,100,0,0,100,0,0,100];
Vary = Sys0;
Exp.ev = [0,0.355,0.457,0.497,1.576,1.577,1.592,1.629,1.632,2.97,2.98,3.002,3.004,
          3.01,3.038,3.821,3.824,3.827,3.837,3.856,3.879,3.888,3.895,3.903];
```

149 Note that only 24 eigenvalues were found experimentally, so this will form a partial least squares inverse eigenvalue problem (LSIEP). To find the solution system is as simple as:

```
SysOut = INS_IEP(Sys0,Vary,Exp);
```

151 It is possible to find multiple minimising systems even if they do not make any sense physically, however due to the scaling of the problem a change in the default deflation parameters is necessary:

```
Opt = struct('NDeflations',4,'Sigma',1e-7);
SysOut= INS_IEP(Sys0,Vary,Exp,Opt);
```

154 The output contains four different spin systems that all have the same eigenvalues as input, one is the original solution up to a change of sign of the B_2^2 parameter, and all have the same exchange term.

157 Additional examples can be found in the Examples folder. A full list of options is provided in the help of INS_IEP.
